Abstract

Self-similarity of random trees is related to the operation of pruning. Pruning \( \mathcal{R} \) cuts the leaves and their parental edges and removes the resulting chains of degree-two nodes from a finite tree. A Horton–Strahler order of a vertex \( v \) and its parental edge is defined as the minimal number of prunings necessary to eliminate the subtree rooted at \( v \). A branch is a group of neighboring vertices and edges of the same order. The Horton numbers \( N_k[K] \) and \( N_{ij}[K] \) are defined as the expected number of branches of order \( k \), and the expected number of order-\( i \) branches that merged order-\( j \) branches, \( j > i \), respectively, in a finite tree of order \( K \). The Tokunaga coefficients are defined as \( T_{ij}[K] = N_{ij}[K]/N_j[K] \). The pruning decreases the orders of tree vertices by unity. A rooted full binary tree is said to be mean-self-similar if its Tokunaga coefficients are invariant with respect to pruning: \( T_k := T_{i,i+k}[K] \). We show that for self-similar trees, the condition \( \limsup_{K \to \infty} T_{i,i}[K] < \infty \) is necessary and sufficient for the existence of the strong Horton law: \( N_k[K]/N_1[K] \to R^{-k} \), as \( K \to \infty \) for some \( R > 0 \) and every \( k \geq 1 \).

1. INTRODUCTION

Horton laws, which are akin to a power-law distribution of the element sizes in a branching system, epitomize the scale invariance of natural dendritic structures. It is very intuitive that the existence of Horton laws should be related to the self-similar organization of branching, defined in suitable terms. Such relation, however, has escaped a rigorous explanation, remaining for long time a part of science literature folklore.\(^1\) This paper shows that a weak (mean) invariance under the operation of tree pruning is sufficient for the Horton law of branch numbers to hold in the strongest sense, hence explaining and unifying many earlier empirical observations and partial results in this direction.

We work with binary trees, although our results can be easily extended to the case of trees of a higher degree. Recall that pruning of a finite rooted full binary tree \(T\) cuts its leaves (vertices of degree one) and their parental edges, and removes the resulting chains of degree-two vertices and their parental edges (so-called series reduction). The Horton–Strahler order \(k\) of a vertex \(v\) is the minimal number of prunings necessary to eliminate the subtree rooted at \(v\). A branch is a sequence of neighboring vertices and their parental edges of the same order. We write \(N_k\) for the total number of branches of order \(k\) in a tree. A common empirical observation in the natural dendritic structures is that \(N_{k+1}/N_k \approx R,\) \(3 \le R \le 5\). This regularity was first described by Horton\(^4\) in a study of river streams; it has been strongly corroborated in hydrology\(^5,9\) and expanded to biology and other areas\(^10\) since then. Similar relations, referred to as Horton laws, are reported for selected metric quantities, for example the average lengths of river streams \((l_{k+1}/l_k \approx R)\), average contributing areas of order-\(k\) drainage basins \((A_{k+1}/A_k \approx R_A)\), etc.

Informally, Horton laws suggest that the branch order \(k\) is proportional to the logarithm of a suitably defined “size” \(S_k\) of the branch: \(S_k \propto R^k\). A geometric distribution of the branch counts \(N_k\):

\[
P(a \text{ random branch has order } \ge k) = R^{-k}
\]

is equivalent to a power-law distribution of branch sizes:

\[
P(S_k \ge x) \propto x^{-\alpha}, \quad \alpha = \ln(R)/\ln(B).
\]

Hence, the empirical Horton laws can be interpreted as a power-law distribution of system element sizes. This might hint at a scale-invariant organization of the respective branching structures, as power laws often accompany fractality.

For long time, the only rigorous result on validity of Horton laws was that of Shreve,\(^11\) who demonstrated that in a uniform distribution of rooted binary trees with \(n\) leaves (that he called topologically random networks), the ratio \(N_{k+1}/N_k\) converges to \(4\) as \(n\) goes to infinity. This model is equivalent to the critical binary Galton-Watson tree conditioned to have \(n\) leaves.\(^{12,13}\) Shreve also showed that in a topologically random network the average number \(T_{ij}\) of side-branches of order \(i\) per branch of order \(j\) only depends on the relative ordering of the branches: \(T_{ij} = 2^{j-i-1}\), as the tree size increases. We notice that pruning decreases the order of every branch by unity. Accordingly, Shreve’s result implies, in particular, that the average numbers \(T_{ij}\) are invariant under the pruning operation: \(T_{ij} = T_{i-j-1}\). The topologically random network was hence the first example of a model that obeys both the Horton law of branch numbers and structural invariance with respect to pruning. The invariance with respect to pruning is called self-similarity, and may refer to the invariance of distributions, or the means of selected statistics (like is the case with Shreve’s result).

Tokunaga\(^14\) introduced a broader class of mean-invariant models defined by the constraint \(T_{ij} = T_{j-i-1} = a c^{j-i-1}\) for positive \(a, c\). The validity of the Tokunaga constraint has been empirically confirmed in numerous observed and modeled systems,\(^7,10,15–17\) notably including diffusion limited aggregation,\(^15,18\) and two-dimensional site percolation.\(^19\) Furthermore, Burd et al.\(^13\) demonstrated that the Tokunaga constraint with \((a, c) = (1, 2)\) is the characteristic property of critical binary offspring distribution within the class of Galton-Watson (non-necessarily binary) trees, and that the

Keywords: Random Trees; Horton Law; Tokunaga Self-Similarity.
critical binary Galton–Watson trees are also distributionally invariant with respect to pruning. Zaliapin and Kovchegov have shown that both Horton law with \( R = 4 \) and the Tokunaga constraint with \((a,c) = (1,2)\) hold in a level-set tree representation of a symmetric random walk, and that in general such a tree is not equivalent to the critical binary Galton–Watson model.

McConnell and Gupta have shown that the Tokunaga constraint is sufficient for a Horton law. Specifically, they proved that if the sequence of branch counts \( N_k \) is related to the Tokunaga coefficients \( T_k = a c^{k-1} \) via the recursive counting equation

\[
N_k = 2 N_{k+1} + \sum_{j=1}^{K-2} T_j N_{k+j} \quad 1 \leq k \leq K-1, \quad K \geq 2,
\]

then \( N_{v+1}/N_v \to R \) for any \( v \geq 1 \) in the limit of large-order trees. In this case

\[
R = 2 + a + c + \sqrt{(2 + a + c)^2 - 8c},
\]

which was reported earlier (under the explicit assumption that Horton law holds) by Tokunaga, Peckham, and others.

Equation (2) suggests that different Horton exponents \( R \) can be easily attained by using the Tokunaga side-branching with different pairs \((a,c)\). At the same time, most of the existing rigorous results on the Horton laws in “natural” models (not formulated explicitly in terms of Horton branch counting) refer to the models equivalent to the Galton–Watson critical binary tree or its slight ramifications, with \( R = 4 \), or to trees with no side-branching and \( R = 2 \). Recently, the authors established a weak version of the Horton law for the tree that describes the celebrated Kingman’s coalescent process; this system has \( R = 3.043827 \ldots \).

This study expands the sufficient conditions for the Horton law (in its strong version defined in Sec. 2.4) to all sequences of side-branch coefficients such that \( \limsup_j T_j^{1/k} < \infty \). We also show that this condition is necessary in the class of mean self-similar trees. The Horton exponent in this case is given by \( R = 1/\omega_0 \), where \( \omega_0 \) is the only real root of

\[
(\omega) = -1 + 2\omega + \sum_{k=1}^{\infty} \omega^k \frac{\omega}{k}
\]

within the interval \([0, 1/2]\), which was conjectured by Peckham. The results are obtained in a probabilistic setting and refer to the expectations of branch counts with respect to a probability measure on the space of finite rooted full binary trees of Horton–Strahler order \( K \), as \( K \) increases. This setup allows us to relax the assumption of similar statistical structure of side-branching within each branch, which is a typical assumption in the studies of Horton laws and tree self-similarity.

We start by reviewing the essential definitions in Sec. 2. Section 3 introduces self-similar trees in a probabilistic setting, and establishes the equivalence of prune-invariance and the constraint \( T_{ij} = T_{j-i} \). The main results are proven in Sec. 4.

2. PRELIMINARIES

2.1. Rooted Trees

Recall that a simple graph is a collection of vertices connected by edges in such a way that each pair of vertices may have at most one connecting edge and there is no self-loops. A tree is a connected simple graph without cycles. In a rooted tree, one node is designated as a root; this imposes the parent–child relationship between the neighbor vertices. Specifically, of the two neighbor vertices the one closest to the root is called parent, and the other — child. In a rooted tree, each non-root vertex has the unique parental edge that connects this vertex to its parent. A leaf is a vertex with no children. The space of finite unlabeled rooted full binary trees, including the empty tree \( \emptyset \), is denoted by \( T \). All internal vertices in a tree from \( T \) have degree 3, leaves have degree 1, and the root has degree 2.

2.2. Tree Pruning

Pruning of a tree is an onto function \( R : T \to T \), whose value \( R(T) \) for a tree \( T \neq \emptyset \) is obtained by removing the leaves and their parental edges from \( T \), and then compressing the resulting tree from \( T \) by removing all degree-two chains (this operation is known as series reduction). We also set \( R(\emptyset) = \emptyset \).

2.3. Horton–Strahler Orders

The Horton–Strahler ordering of the vertices and edges of a finite rooted binary tree \( T \in T \) is related to the iterations \( R^k \) of the pruning operation. Specifically, a vertex \( v \in T \) and its parental edge have order \( k = 1, 2, \ldots \) if the subtree \( \tau_v \in T \)
rooted at \( v \) is eliminated during the \( k \)th iteration of pruning:
\[
k(v) = \min_{k \geq 1}(R_k(v) = \phi).
\]
The order \( k(T) \) of a non-empty tree coincides with the maximal order of its vertices. We also set \( k(\phi) = 0 \). A branch is defined as a union of neighboring vertices and edges of the same order. Figure 1 illustrates the operation of pruning and the definition of Horton–Strahler orders.

Equivalently, the Horton–Strahler ordering can be done by hierarchical counting.6,10,13 In this approach, each leaf is assigned order \( k(\text{leaf}) = 1 \). An internal vertex \( p \) whose children have orders \( i \) and \( j \) is assigned the order
\[
k(p) = \max(i, j) + \delta_{ij},
\]
where \( \delta_{ij} \) is the Kronecker’s delta. The parental edge of a vertex has the same order as the vertex.

2.4. Horton Law

Let \( T_K, K \geq 1 \), be the subspace of finite binary trees of Horton–Strahler order \( K \). Consider a set of probability measures \( \{\mu_K\} \) for \( K \geq 1 \), each of which is defined on \( T_K \), and write \( E_K(\cdot) \) for the mathematical expectation with respect to \( \mu_K \). Let \( N_k = N_k(T) \) be the number of branches of order \( k \) in a tree \( T \in T \). We define the average Horton numbers, which are the main object for our analysis:
\[
\mathcal{N}_k[K] = E_K(N_k), \quad 1 \leq k \leq K, \quad K \geq 1.
\]

Definition 1. We say that a sequence of measures \( \{\mu_K\} \) satisfies a strong Horton law if
\[
\lim_{K \to \infty} \frac{\mathcal{N}_k[K]}{\mathcal{N}_k[1]} = R^{1-k} < \infty \quad \text{for any } k \geq 1.
\]

2.5. Tokunaga Coefficients

Let \( N_{ij} = N_{ij}[T] \) denote the number of instances when an order-\( i \) branch merges with an order-\( j \) branch, \( 1 \leq i < j \), in a tree \( T \). Such branches are referred to as side-branches of order \( i \). Define the respective expectation \( \mathcal{N}_{ij}[K] = E_K(N_{ij}) \). The Tokunaga coefficients \( T_{ij}[K] \) for subspace \( T_K \) are defined as
\[
T_{ij}[K] = \frac{\mathcal{N}_{ij}[K]}{\mathcal{N}_{ij}[1]}, \quad 1 \leq i < j \leq K. \quad (3)
\]

Remark 1. Consider a situation when every branch of order \( j \) has the same expected number \( S_j \) of side-branches of order \( i < j \). Then
\[
\mathcal{N}_{ij}[K] = E_K(N_{ij}) = E_K(E_K(N_{ij}|N_j)) = E_K(N_j S_j) = S_j E_K(N_j) = S_j \mathcal{N}_j[K],
\]
and hence
\[
T_{ij}[K] = \frac{\mathcal{N}_{ij}[K]}{\mathcal{N}_j[1]} = S_j.
\]
Such framework was considered by Shreve,26 Tokunaga,14 Burd et al.,13 and others. Our definition (3)
includes this situation as a special case, although in general it is free of the assumption of similar statistical structure of individual branches.

3. SELF-SIMILAR TREES

Definition 2. A set of measures \( \{ \mu_K \} \) on \( \{ T_K \} \) is called coordinated if \( T_i := T_{ij}[K] \) for all \( K \geq 2 \) and \( 1 \leq i < j \leq K \).

For a set of coordinated measures \( \{ \mu_K \} \), the Tokunaga matrix \( T_K \) for any \( K \) forms a \( K \times K \) matrix

\[
T_K = \begin{bmatrix}
0 & T_{1,2} & T_{1,3} & \ldots & T_{1,K} \\
0 & 0 & T_{2,3} & \ldots & T_{2,K} \\
0 & 0 & \ddots & \ddots & \vdots \\
\vdots & \ddots & \ddots & 0 & T_{K-1,K} \\
0 & 0 & 0 & 0 & 0
\end{bmatrix}
\]

which coincides with the restriction of any larger-order Tokunaga matrix \( T_M \), \( M > K \), to the first \( K \times K \) entries.

Definition 3. A collection of coordinated probability measures \( \{ \mu_K \} \) on \( \{ T_K \} \) is called (mean) self-similar if \( T_i = T_{ij}[K] \) for some sequence \( T_k \geq 0 \), \( k = 1, 2, \ldots \), and any \( K \geq 2 \). The elements of the sequence \( T_k \) are also referred to as Tokunaga coefficients, which does not create confusion with \( T_{ij} \).

For a self-similar collection of measures, the matrix of Tokunaga coefficients becomes Toeplitz:

\[
T_K = \begin{bmatrix}
0 & T_1 & T_2 & \ldots & T_{K-1} \\
0 & 0 & T_1 & \ldots & T_{K-2} \\
0 & 0 & \ddots & \ddots & \vdots \\
\vdots & \ddots & \ddots & 0 & T_1 \\
0 & 0 & 0 & 0 & 0
\end{bmatrix}
\]

A variety of self-similar measures can be constructed for an arbitrary sequence of Tokunaga coefficients \( T_k > 0 \), \( k \geq 1 \). Next, we give one natural example.

Example 1. Independent Random Attachment. The subspace \( T_1 \), which consists of a single-vertex tree, possesses a trivial unity mass measure. To construct a random tree from \( T_2 \), we select a discrete probability distribution \( P_2[m] \), \( m = 0, 1, \ldots \), with the mean value \( T_1 \). A random tree \( T \) in \( T_2 \) is obtained from the single-vertex tree \( T_1 \) of order 1 via the following two operations. First, we attach two child vertices to the only vertex of \( T_1 \). This creates a tree of order 2 with no side-branches — two leaves attached to the root. Second, we draw the number \( N_{1,2} \) from the distribution \( P_{1,2} \), and attach \( N_{1,2} \) vertices to this tree so that they form side-branches of order \( 1 \).

In general, to construct a random tree from \( T_K \) for \( K \geq 2 \) we select a set of discrete probability distributions \( P_{k,K}(n) \), \( k = 1, \ldots, K-1 \), with the respective mean values \( T_k \). A random tree \( T \) in \( T_K \) is constructed in iterative fashion, starting from the single-vertex tree \( T_1 \) and increasing its order by adding new vertices. Specifically, to construct a random tree \( T_k \) of order \( k \geq 2 \) from a random tree \( T_{k-1} \) of order \( k-1 \), we perform the following operations. First, add two new child vertices to every leaf of \( T_{k-1} \) hence producing a tree \( T_2 \) of order \( k \) with no side-branches of order 1. Second, for each branch of order 2 \( \leq j \leq k \) in \( T_2 \) draw a random number \( N_{1,j} \) from the distribution \( P_{j-1,K} \) and attach \( N_{1,j} \) new child vertices to this branch so that they form side-branches of order 1. Each new vertex is attached in random order with respect to the existing side-branches. Specifically, we notice that \( s \geq 0 \) side-branches attached to a branch of order \( j \) are uniquely associated with \( s+1 \) edges within this branch. (When discussing the single branch of the maximal order \( k \), we count one “imaginary” edge parental to the tree root.) The attachment of the new \( N_{1,j} \) vertices among the \( s+1 \) edges is given by the equiprobable multinomial distribution with \( s+1 \) categories and \( N_{1,j} \) trials.

According to Remark 1, the self-similarity condition \( T_{i+j+1}[K] = T_i \) holds within each subspace \( T_K \), \( K \geq 2 \). Notice that pruning defines a down-shift of the order subspaces, that is for \( K \geq 1 \)

\[
R(T_K) = T_{K-1}.
\]

Moreover, pruning decreases the Horton–Strahler order of each vertex (and hence of each branch) by unity; in particular

\[
N_k[T] = N_{k-1}[R(T)], \quad k \geq 2, \quad (4)
\]

\[
N_j[T] = N_{j-1,j-1}[R(T)], \quad 2 \leq i < j. \quad (5)
\]

This shift property allows us to establish connection between the values of Tokunaga coefficients for different orders \( K \). Specifically, consider measure \( \mu_K^R \) induced on \( T_K \) by the pruning operator

\[
\mu_K^R(A) = \mu_{K+1}(R^{-i}(A)) \quad \forall A \subset T_K.
\]
The Tokunaga coefficients computed on $T_K$ using the induced measure $\nu^K_R$ are denoted by $T^K_{ij}[K]$.

**Definition 4.** A collection of coordinated probability measures $\{\mu_K\}$ on $[T_K]$ is called self-similar if $T^n_{ij}[K] = T^0_{ij}[K]$ for any $K \geq 2$ and all $1 \leq i < j \leq K$.

**Lemma 1.** The Definitions 3 and 4 are equivalent.

**Proof.** The pruning-related index shift (4),(5) implies

$$T_{i+1,j+1}[K+1] = T^K_{ij}[K].$$

If a coordinated set of measures $\{\mu_K\}$ satisfy Definition 3, then

$$T_{i+1,j+1}[K+1] \overset{\text{Def}}{=} T_{ij}^{R[K]}[K] \overset{\text{coordination}}{=} T^K_{ij}[K].$$

Together with (6), this implies $T_{ij}[K] = T^K_{ij}[K]$, which means that Definition 4 is also satisfied. 

If a coordinated set of measures $\{\mu_K\}$ satisfy Definition 4, then

$$T_{ij}[K] \overset{\text{Def}}{=} T^K_{ij}[K] \overset{\text{coordination}}{=} T_{i+1,j+1}[K+1].$$

Hence

$$T_{i+1,j+1}[K] = T_{ij}[K] = \cdots = T_{i,j+i+1}[K] =: T_{ij}.$$ 

which means that Definition 3 is also satisfied. \Box

**4. RESULTS**

Consider a set of self-similar measures $\{\mu_K\}_{K \geq 1}$ with Tokunaga coefficients $T_K$. We define the vector of Horton indices as

$$\zeta_K = \begin{pmatrix} N[1][K] \\ N[2][K] \\ \vdots \\ N[K][K] \end{pmatrix}.$$ 

We also define the vector of normalized Horton indices in $\mathbb{R}^n$,

$$\xi_K := \frac{1}{\zeta_K} \begin{pmatrix} \zeta_K \\ 0 \\ \vdots \\ 0 \end{pmatrix} = \begin{pmatrix} N[1][K]/N[1][K] \\ \vdots \\ N[K][K]/N[K][K] \end{pmatrix}.$$ 

The average number of side-branches of order $1 \leq i < K$ within $T_K$ is $N_i[K] = 2N_{i+1}[K]$. At the same time, the number of side-branches of order $i$ can be computed by counting the side-branches of order $i$ for all larger-order branches:

$$\sum_{j=i+1}^{K} T_{ij}N_j[K] = \sum_{m=1}^{K-i} T_{im}N_{i+m}[K].$$

and therefore the vector of side-branches is $T_K \zeta_K$.

Thus

$$T_K \zeta_K = \begin{pmatrix} 1 & -2 & 0 & \cdots & 0 \\ 0 & 1 & -2 & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & 0 \\ 0 & 0 & \cdots & 1 & -2 \\ 0 & 0 & \cdots & 0 & 0 \end{pmatrix} \zeta_K. \quad (7)$$

This can also be written as

$$N_i[K] = 2N_{i+1}[K] + \sum_{j=1}^{K-i} T_{ij}N_{i+j}[K], \quad 1 \leq k \leq K-1, \quad K \geq 2, \quad (8)$$

which is a probabilistic (mean) version of a deterministic counting equation (1).

Next, define

$$G_K := \begin{pmatrix} -1 & T_1 + 2 & T_2 & \cdots & T_{K-1} \\ 0 & -1 & T_1 + 2 & \cdots & T_{K-2} \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & -1 & T_1 + 2 \\ 0 & 0 & \cdots & 0 & -1 \end{pmatrix}$$

which is a $K \times K$ restriction of the following infinite dimensional linear operator to the first $K$ dimensions:

$$G := \begin{pmatrix} -1 & T_1 + 2 & T_2 & \cdots \\ 0 & -1 & T_1 + 2 & \cdots \\ 0 & 0 & -1 & T_1 + 2 & \cdots \\ 0 & 0 & 0 & -1 & \ddots \\ \vdots & \vdots & \vdots & \ddots & \ddots \end{pmatrix} \quad (9)$$

1650017-6
Equation (7) implies \( G_K \xi_K = -\varepsilon_K \), the \( K \)th coordinate basis vector, and therefore
\[
\begin{pmatrix}
\xi_{K+1}(2) \\
\xi_{K+1}(3) \\
\vdots \\
\xi_{K+1}(K+1)
\end{pmatrix} = -G_K^{-1} \varepsilon_K = \begin{pmatrix}
\xi_K(1) \\
\xi_K(2) \\
\vdots \\
\xi_K(K)
\end{pmatrix}
\tag{10}
\]
Thus we proved the following.

**Proposition 1.** Let \( \{\mu_K\} \) be a set of self-similar measures on \( \{T_K\} \). Then for any \( K \geq 1 \) and \( 1 \leq j \leq K \),
\[
N_{j+1}(K+1) = \xi_{K+1}(j+1) = \xi_K(j) = N_j[K].
\]
Accordingly, we also have
\[
N_{j+1,A}(K+1) = N_j[A],
\]
where \( A = (1, 2, \ldots, j) \).

Observe that \( G_K \xi_K = -\varepsilon_K \), where, by construction, \( \xi_K(1) = N_1[K] \geq (T_1 + 2)^{K-1} \). The following proposition formalizes the condition required for \( \lim_{K \to \infty} \xi_K = \xi \), where \( \xi \) satisfies \( G \xi = 0 \) with coordinates \( \xi(j) = R^{j-1} \). Finally, Theorem 1 at the end of this section provides a complete analysis of \( \xi_K \) in terms of the sequence \( T_j \) of Tokunaga coefficients.

**Proposition 2.** Let \( \{\mu_K\} \) be a set of self-similar measures on \( \{T_K\} \). Suppose that the limit
\[
R = \lim_{K \to \infty} \frac{\zeta_{K+1}(1)}{\zeta_K(1)} = \lim_{K \to \infty} \frac{N_1[K+1]}{N_1[K]} \tag{11}
\]
exists and is finite. Then, the strong Horton law holds; that is, for each positive integer \( j \)
\[
\xi(j) = \lim_{K \to \infty} \xi_K(j) = \lim_{K \to \infty} \frac{N_j[K]}{N_1[K]} = R^{j-1}.
\]
Conversely, if the limit (11) does not exist, then neither will \( \lim_{K \to \infty} \xi(j) \). That is, the limit \( \lim_{K \to \infty} \xi_K(j) \) does not exist at least for some \( j \).

**Proof.** Suppose that the limit \( R = \lim_{K \to \infty} \frac{\zeta_{K+1}(1)}{\zeta_K(1)} \) exists and is finite. Proposition 1 implies for any fixed integer \( m \geq 1 \),
\[
\frac{\zeta_K(m+1)}{\zeta_K(m)} = \frac{\zeta_{K+1}(1)}{\zeta_K(1)} \to R^{-j}.
\]
Thus, for any fixed integer \( j \geq 2 \),
\[
\zeta_K(j) = \frac{\zeta_{K}(j)}{\zeta_{K}(1)} = \prod_{m=1}^{j-1} \frac{\zeta_{K}(m+1)}{\zeta_{K}(m)} \to R^{-j}.
\]
Conversely, suppose the limit \( \lim_{K \to \infty} \frac{\zeta_{K+1}(1)}{\zeta_{K}(1)} \) does not exist. Then, taking \( j = 2 \), we obtain
\[
\zeta_K(2) = \prod_{m=1}^{1} \frac{\zeta_{K}(m+1)}{\zeta_{K}(m)} \to \text{diverges}
\]
by Proposition 1. Thus, \( \lim_{K \to \infty} \zeta_K(2) \) diverges.

**Remark 2.** The conditions of Proposition 2 can be somewhat relaxed. Specifically, we only use the self-similarity requirement to prove the shift equality (10). Hence, this equality together with the existence of the limit (11) suffices to obtain the strong Horton law.

### 4.1. Expressing \( \zeta_K(1) \) from \( \{T_j\} \)

In this section, we express \( \zeta_K(1) \) in terms of the elements of the Tokunaga sequence \( \{T_j\}_{j=1,2, \ldots} \) under the assumption of a “tamed” Tokunaga sequence: \( \lim_{j \to \infty} T_j^{1/2} < \infty \). We define
\[
t(i) = \begin{cases} 
-1 & i = 0, \\
T_i & i = 1, \\
T_i + 2 & i \geq 2
\end{cases}
\]
and let \( \zeta(z) = \sum_{j=0}^{\infty} z^j t(j) \). The quantity \( \zeta_K(1) \) can be computed by counting, and expressed via convolution products as follows:
\[
\zeta_K(1) = \sum_{r=1}^{K} \sum_{j_1+j_2+\ldots+j_r=K} \zeta_K(j_1) t(j_2) \cdots t(j_r)
\]
where \( \delta_0(j) \) is the Kronecker delta, and therefore, \( (t + \delta_0)(0) = 0 \). Hence, taking the \( z \)-transform of
Y. Kovchegov & I. Zaliapin

Next we show that \( \theta = 0 \). Suppose not. Then

\[
0 = -1 + 2r \cos(\theta) + \sum_{j=1}^{\infty} r^j T_j \cos(j\theta)
\]

\[
< -1 + 2r + \sum_{j=1}^{\infty} r^j T_j = -1 + 2v_0 + \sum_{j=1}^{\infty} w_0^j T_j = 0
\]

arriving to another contradiction. Hence \( r = v_0 \), \( \theta = 0 \), and \( w = w_0 \).

Let \( w_0 \) denote the only root of \( \tilde{l}(z) \) in the real line subinterval \( (0, \frac{1}{2}) \) as in Lemma 2. Recall that the radius of convergence \( L = \limsup_{j \to \infty} r_j^{1/2} \) of \( \tilde{l}(z) = -1 + 2z + \sum_{j=1}^{\infty} z^j T_j \) is greater than \( w_0 \). Then, following Lemma 2, there is a positive real \( \gamma \in (w_0, L) \) such that

\[
\gamma < w \quad \text{for all } w \neq w_0 \text{ such that } \tilde{l}(w) = 0. \tag{14}
\]

Now, (14) implies for \( 0 < \theta < w_0 \),

\[
\zeta_{K+1}(1) = \frac{1}{2\pi i} \oint_{|z|=\gamma} \tilde{l}(z)^{1/2} \, dz
\]

\[
= -\text{Res} \left( \frac{1}{\tilde{l}(z)^{1/2}} \right) - \frac{1}{2\pi i} \oint_{|z|=\gamma} \frac{dz}{(\tilde{l}(z)^{1/2})^2}
\]

Observe that \( \text{Res}(\frac{1}{\tilde{l}(z)^{1/2}}) \) is a constant multiple of \( \frac{1}{w_0} \) since \( w_0 \) is a root of \( \tilde{l}(z) \) of algebraic multiplicity one. Thus, since \( w_0 < \gamma \) and

\[
\left| \frac{\zeta_{K+1}(1)}{\zeta_{K}(1)} \right| = \left| \frac{\zeta_{K+1}(1)}{\zeta_{K}(1)} \right| = \frac{1}{w_0} \quad \text{as } K \to \infty.
\]

Hence Proposition 2 will imply the following lemma.

**Lemma 3.** Suppose \( \limsup_{j \to \infty} r_j^{1/2} < \infty \). Then, for each positive integer \( j \), the limit

\[
\xi(j) = \lim_{K \to \infty} \zeta_{K}(j)
\]

exists, and \( \xi(j) = w_0^{-1} \).
The converse is also true. Specifically, suppose the limit
\[ R = \lim_{k \to \infty} \frac{\xi_{k+1}(1)}{\xi_k(1)} \]
exists and is finite. Then, since \( \xi_k(1) \geq T_{j_k}^k \) for all \( j \in \mathbb{N} \) and \( k \in \mathbb{N} \),
\[ \lim_{j \to \infty} T_{j_k}^k \leq \lim_{k \to \infty} [\xi_k(1)]^{1/k} = R < \infty. \]
Hence, we have proven another lemma.

**Lemma 4.** Suppose \( \limsup_{j \to \infty} T_{j_k}^k = \infty \). Then, the limit \( \lim_{K \to \infty} \xi_K(j) \) does not exist at least for some \( j \).

We now combine the results in Lemmas 3 and 4 into the following theorem.

**Theorem 1.** Suppose \( \limsup_{j \to \infty} T_{j_k}^k < \infty \). Then, for each positive integer \( j \)
\[ \xi(j) = \lim_{K \to \infty} \xi_K(j) = \lim_{K \to \infty} \frac{N_{j}[R]}{N_{j}[R]} = R^{1-\frac{1}{j}}, \]
where \( 1/R = w_0 \) is the only real root of the function \( t(z) = -1 + 2z + \sum_{j=1}^{\infty} xT_j \) in the interval \( (0, \frac{1}{2}) \).
Conversely, if \( \limsup_{j \to \infty} T_{j_k}^k = \infty \), then the limit \( \lim_{K \to \infty} \xi_K(j) = \lim_{K \to \infty} \frac{N_{j}[R]}{N_{j}[R]} \) does not exist at least for some \( j \).

We notice that the fact that \( R \) is reciprocal to the solution of \( t(z) = 0 \) was noticed by Peckham\(^6\) under the assumption \( N_{j_k} \sim e^{R^{1-\frac{1}{j}}} \) as \( K \to \infty \).

Below we give several examples of Theorem 1.

**Example 1.** Shallow side-branching. Suppose \( T_k = 0 \) for \( k \geq 3 \), that is we only have "shallow" side-branches of orders \( j \geq 2 \) and \( j \geq 1 \). Then
\[ \hat{t}(z) = 1 + \frac{1}{T_1 + 2} z + T_2 z^2. \]
The only root of this equation within \( [0, 1/2] \) is
\[ w_0 = \frac{\sqrt{(T_1 + 2)^2 + 4T_2} - (T_1 + 2)}{2T_2}, \]
which leads to
\[ R = \frac{1}{w_0} = \frac{\sqrt{(T_1 + 2)^2 + 4T_2} + (T_1 + 2)}{2T_2}. \]
In particular, if \( T_k = 0 \) for \( k \geq 2 \), then \( R = T_1 + 2 \); such trees are called "cyclic".\(^6\) This shows that the entire range of Horton exponents \( 2 \leq R < \infty \) can be achieved by trees with only very shallow side-branching. This also shows that \( T_1 \geq 1 \) leads to \( R \geq 3 \), which seems to be the case for most of the observed branching systems.

**Example 2.** Tokunaga self-similarity, suppose \( T_j = a \cdot c^{j-1} \), where \( a, c > 0 \). This model received considerable attention in the literature\(^6,14,23\) in part because of its ability to closely describe river networks.\(^{17}\) Here we have
\[ \hat{t}(z) = -1 + 2z + a\sum_{j=1}^{\infty} (cz)^{j-1} \]
which leads to
\[ \frac{1}{t(z)} = \frac{1-cz}{1-(a+c+2)z-2cz^2} \]
and the discriminant is positive, \( (a+c+2)^2 - 8c > (c+2)^2 - 8c = (c-2)^2 \geq 0 \). Therefore, there will be two positive roots, \( p_1 > p_2 \) of the denominator
\[ 1 - (a+c+2)z - 2cz^2, \]
and
\[ T = \frac{1}{2(p_1 - p_2)(z - p_1)} - \frac{1}{2(p_1 - p_2)(z - p_2)} \]
Thus, since \( \frac{1}{p_2} = \sum_{k=0}^{\infty} \frac{1}{p_2^{k+1}} \) for \( |z| < |p| \), formula (13) implies
\[ \xi_{K+1}(1) = \frac{1}{2(p_1 - p_2)} \left( 1 - c p_2 \right) \right) \frac{1 - c p_1}{p_1^{k+1}} \right) \right) \] (15)
for \( |z| \) small enough, where one can easily check that \( 1 > cp_1 \). Therefore, the conditions of Proposition 2 are satisfied with
\[ R = p_2 = \frac{a + c + 2 - \sqrt{(a+c+2)^2 - 4c}}{4c}. \]
Hence,
\[ R = \frac{a + c + 2 + \sqrt{(a+c+2)^2 - 8c}}{2} \] (16)
as in earlier works\(^6,14,23\). Also, in agreement with the Lemma 3, \( w_0 = p_2 = \frac{1}{R} \).

**Example 3.** “Differentiated Tokunaga” self-similarity. Suppose \( T_j = a \cdot j \cdot c^{j-1} \), where \( a, c > 0 \).

Y. Kovchegov & I. Zaliapin

Then
\[
\hat{t}(z) = -1 + 2z + az \sum_{j=1}^{\infty} j(\alpha_j z)^{-1} = -1 + 2z + \frac{az}{(1-cz)^2} = \frac{2z^2 - 3 - (c+4)z^2 + (a+2c+2)z - 1}{(1-cz)^2}.
\]

Here \( \frac{1}{z} = w_0 \) is the smallest positive real root of polynomial
\[
p(z) = 2z^2 - 3 - (c+4)z^2 + (a+2c+2)z - 1.
\]
Now, since \( \hat{t}(1/2) > 0 \), \( w_0 \in (0, 1) \). In this example, we cannot derive an explicit formula for \( R = R(a,c) \). However, we solve \( p(w_0) = 0 \) for \( c > 0 \), obtaining the following relation among \( a, c \) and \( R \):
\[
c = \frac{1}{w_0} + \sqrt{\frac{a}{1 - 2cw_0}} = \left( 1 + \sqrt{\frac{a}{R-2}} \right) R.
\]
